Abstract. Transactional isolation is a challenge for polystores, as along with the limited capabilities of each datastore, we have to contend with their sheer diversity. However, transactional isolation is increasingly desirable as a variety of datastores are being sought after for roles that go beyond data lakes. Transactional guarantees are also relevant for reliability at scale. In this paper, we propose that transactional isolation in polystores can be achieved by leveraging the query engine, i.e., basing some of the responsibilities of a traditional transactional storage manager (TSM) on the query language itself. This has the key advantage of greatly simplifying design and implementation, as it doesn't need to be re-invented for each datastore, and should increase performance, by taking advantage of dynamic query optimization where available. We demonstrate the feasibility of the proposal with a simple proof-of-concept and experiment.

Keywords: transactions  $\cdot$  snapshot isolation  $\cdot$  polystores

# 1 Introduction

Polystores aim at combining the diversity of data models, query languages, interfaces, and architectures of multiple datastores [17, 22]. This enables executing queries expressed in, or even combining, the preferred data model, the best query abstractions, and ideal query engines for each use case. The focus has thus been on big data and analytical workloads.

However, diverse data models and query capabilities are not the sole reason for the current datastore diversity. Increasingly, the ability to handle updates in a variety of challenging scenarios has been the driving force behind novel datastore proposals. For instance, Apache Cassandra is well known for its ability to handle very high update throughput [23]. Redis provides a variety of data structures, including Conflict-free Replicated Data Types (CRDTs) for geographical scalability [10].

It is thus interesting to accommodate this diversity in update processing capabilities of datastores, which raises the issue of update consistency and atomicity in each of them and across multiple of them. Transactional updates are also desirable even in mostly static data lakes to correct and remove data (e.g., due

to the GDPR and other "right to be forgotten" regulations) and ultimately for reliability, as data corruption on loading has shown to be a frequent issue [7].

Traditionally, transactional isolation and recovery are the responsibility of the transactional storage manager (TSM) layer [21]. Depending on the strategy used, these are achieved by the combined effect of the lock manager, the buffer pool (i.e., for latching and holding different versions), and the log manager. These features are implemented separately and lie beneath the query engine, which then operates within the abstraction of an isolated and recoverable data space. More recently, transactional isolation has also been provided for NoSQL datastores as a custom middleware layer that wraps the native store [19].

Unfortunately, transactional isolation in polystores is harder than in traditional database systems or homogeneous big datastores, and often identified as a key research challenge [28, 30]. The first issue is that target datastores have wildly different isolation and consistency criteria, and not just different implementations of similar criteria. Namely, some systems, such as MongoDB [26] or Neo4j [5], provide multi-operation isolation and recovery. Other systems, such as HBase, do not offer multi-operation isolation but provide multi-versioning and a re-do log, that can be used for transactional isolation at the middleware level [19]. Still, some systems (e.g., Cassandra [23]) exhibit no isolation at all and offer only eventual consistency [31], which is central to their value proposition as distributed and scalable. The second issue is how to enforce a single transactional context for an operation reading from or updating multiple datastores. Even datastores that have transactional support such as MongoDB or Neo4j do not support XA [1] transaction interfaces for two-phase commit. Therefore, individually wrapping or modifying each datastore with a transactional storage management layer is both unfeasible and undesirable.

In this paper, we assume Snapshot Isolation [9] as the target transactional isolation criterion and the availability of a multi-version optimistic concurrency control mechanism. We divide transactional processing into two main concerns: the first involves capturing write operations and, when commit is requested, validating that there are no write-write conflicts with concurrent transactions; the second is the ability to, at any point during the execution of a given transaction, reconstruct the current snapshot by reconciling values written by previously committed transactions, items updated by the current transaction, and avoiding values written by concurrent transactions. We address only the latter and focus on the computation needed to deliver the snapshot in a polyglot query engine.

Our first requirement is to provide transactional isolation and recovery, while at the same time allowing unfettered access to native stores. This precludes, for instance, cluttering the data with version information. The second requirement stems from the observation that the best approach for computing isolated snapshots varies for different datastores and that an efficient implementation must take advantage of each one's strengths.

The main insights in this paper are that reconstructing a transactional snapshot across a diversity of datastores (1) is itself a polyglot data processing problem and (2) that we can take advantage of an optimizing query engine to make it simpler, portable, and efficient. We are, as the saying goes, "eating our own dog-food."

The rest of this paper is organized as follows: Section 2 describes the background and assumptions for our proposal; Section 3 details the design of a proofof-concept system for transactional snapshot reconstruction; Section 4 evaluates the proposed approach with an experiment; and finally, Section 5 discusses the main conclusions, remaining challenges, and future research directions.

# 2 Background and assumptions

## 2.1 Query processing

We assume as the baseline a cloud multi-datastore query engine such as Cloud-MdsQL [22] offering a SQL-like language that can embed statements in native query languages of diverse datastores as table expressions, i.e., *native table expressions*. It follows the mediator/wrapper architecture from multi-database systems: A logically centralized mediator – the Common Query Engine (CQE) – handles client connections, parses and optimizes queries, and then hands subsets of the resulting plan for each target datastore to each wrapper, that extracts native query fragments or converts relational operators in the plan and handles execution and data transfer.

In practice, this means that ad-hoc views of data from multiple datastores can be defined and used in relational queries. A relational data model, extended with non-atomic list and dictionary types, is used as the target for such views and the domain for queries in the CloudMdsQL common query language. The major advantage of this approach is that it is able to fully exploit the power of each datastore with native queries without having to fully map data to a common data model, while at the same time globally optimizing the composite query, e.g., by pushing down selection predicates, using bind join, performing join ordering, or planning intermediate data shipping.

## 2.2 Versions and snapshot isolation

We assume Snapshot Isolation [9] as the target criterion. In contrast to traditional ANSI isolation levels based on 2-phase locking, using a multi-version concurrency control mechanism has clear advantages for read-only transactions and parallel/distributed systems, and is now widely preferred.

This means that there can be multiple versions of each data item stored at the same time and that a version is visible to a transaction if and only if it was committed before the transaction started. For simplicity, we consider only full Snapshot Isolation, with multi-statement consistency, and not the weaker singlestatement Read Consistency levels that are also available in various systems.

Assuming that the minimum visibility (commit) timestamp for an item is cts and that the maximum (starting) visibility timestamp for a transaction is sts, we can consider these possible states for each usable version of an item:

- Visible-to-All (or Storage): Committed versions labeled with a *cts* that is less than or equal to the starting timestamps *sts* of all currently executing transactions, thus, visible-to-all transactions unless overwritten.
- Visible-to-Some (or Cache): Committed versions labeled with a *cts* that is greater than the starting timestamp *sts* of some currently executing transactions, thus, invisible to such transactions even if not overridden. Keeping these versions separate from those visible-to-all avoids non-repeatable reads.
- Visible-to-One (or Temporary): Uncommitted versions associated with a single transaction. These versions ensure that a transaction reads its own writes and at the same time avoid causing dirty reads in concurrent transactions.

When a version is written, it starts in the visible-to-one state, proceeds to visible-to-some when committed, and eventually becomes visible-to-all as other concurrent transactions finish. Some systems might in fact keep around some obsolete versions, visible-to-none, after a newer visible-to-all version exists.

When reading, a transaction first considers its own visible-to-one versions, then those visible-to-some – considering the timestamp – and finally those visible-to-all. This process, which obtains correct versions for all data items requested by some transaction, is the *snapshot reconstruction* and is the focus of this paper.

This distinction of versions in terms of visibility is not how most multiversion systems are described but is key to our insight in Section 3. Instead, systems are usually described in terms of strategies used to physically store different versions. As an example, PostgreSQL keeps them all in the main heap/file, explicitly tagged with  $t\_xmin$  and  $t\_xmax$  that can be compared to current visibility boundaries, termed the *snapshot*. This avoids copying old data when new versions are added, at the expense of keeping obsolete versions until vacuumed [27, 29]. Oracle labels versions with the *system change number* (SCN) [8, 12] and these reside: in the main heap/file, while visible-to-one and locked, latest visibleto-some, or if visible-to-all; other visible-to-some versions are kept separately in *rollback segments*. This optimizes for short-lived transactions, where a new version quickly becomes visible-to-all. A different example is provided by Google's Spanner, which keeps visible-to-one versions directly in the client in unlogged structures and takes advantage of versioning in BigTable to manage committed versions, visible-to-some or visible-to-all [14].

## 2.3 Simplifying assumptions

Besides snapshot reconstruction, Snapshot Isolation requires precluding concurrent updates to the same item. As an example, Oracle and PostgreSQL rely on aborting transactions in lock queues on commit to ensure that the first committer wins. In distributed systems, such as Omid [19], this is achieved with a centralized validation server. A recovery mechanism is also required and usually relies on logging to ensure atomicity and durability. In this paper, we omit both of these important issues and focus exclusively on the read path for snapshot reconstruction. We make the additional simplifying assumption of not considering the ability of a transaction to read its own writes, i.e., we ignore visible-to-one (or temporary) versions during snapshot reconstruction. Moreover, we assume that all writes are done atomically at commit time, as this simplifies representation and the manipulation of timestamps. Our proposal could be extended to accommodate such possibilities, although the current simpler form would already be useful and is actually how some systems work [14].

# 3 Proof-of-Concept

#### 3.1 Version representation

The first pillar of our proposal is the use of regular tables or collections to hold versions of data items in different visibility categories according to Section 2.2, in contrast to using custom data structures encapsulated within a transactional storage manager layer. In detail, we separate visible-to-all (or storage) from visible-to-some (or cache) versions. The approach could be extended by considering a third table or collection for visible-to-one (or temporary) versions, which we are not addressing in this proof-of-concept.

Our key insight, which makes our proposal suitable for a polystore and compatible with a wide spectrum of datastores, is the following: It is not necessary to keep individual version numbers for visible-to-all (or storage) versions. The reason for this is that, by definition, all these versions are visible to all transactions unless overwritten. Therefore, their final visibility depends only on whether reconstruction picks up a more recent version while traversing cached (visible-to-some) versions. In other words, it is as if we consider that all storage (visible-to-all) versions are implicitly labeled with ts - 1, where ts is the oldest version in cache (visible-to-some).

The first corollary is that a transactional update and query system can be layered on top of an existing datastore without changing its content, in particular, without polluting data with additional version meta-data or multiple versions for each item, which would break compatibility with existing non-transactional applications. Additionally, this also decreases the space overhead imposed on the system, comprised by recently modified rows. With a sufficiently large storage, this overhead can be considered effectively zero. The second corollary is that the datastore does not need to be able to filter versions, which is hard or even impossible to do in pure key-value stores. In fact, previous transaction isolation systems that can be layered on existing datastores, such as Spanner [14] or Omid [19], assume that the datastore can hold and filter versions or, in the latter, store additional version meta-data with each item.

In detail, our general approach is that for each storage table (S) in any of the supported datastores, we create an additional table for the corresponding visible-to-some versions  $(S\_Cache)$ . The cache accommodates data with the original schema plus three extra fields: *from* and *to*, which specify a record's validity, and *deleted*, which identifies deleted records. The primary key for this table

a) S	b) S_Cache	c) S <sub>-</sub> Snapshot			
k v	k v from to deleted	$\overline{k  v}$			
<b>k1</b> v1	<b>k1</b> v01 1 4 false	<b>k1</b> v10			
$\mathbf{k2}$ v2	<b>k1</b> v10 5 20 false	<b>k2</b> v2			
<b>k3</b> v3	<b>k1</b> v100 21 $\infty$ false	<b>k4</b> v4			
<b>k4</b> v4	<b>k3</b> $\perp$ 4 $\infty$ true				

Fig. 1: Example of the cache of storage S ( $S\_Cache$ ) and resulting snapshot for transaction T. T's starting timestamp = 15, meaning it will read (k1, v10) and  $(k3, \perp)$  from the cache and the remaining records from the storage. k3 will not be present in the snapshot since it is flagged as deleted.

is composite, with the original key in the base storage table and *from*. As this table is not used by non-transactional applications, and only indirectly by transactional applications, the additional data do not create a compatibility issue.

Figure 1 provides an example. Figure 1(a) shows some base storage table S with key k and value v. Depending on the application and the underlying datastore, both k and v can be composite values. The base table contains items with keys k1 to k4 with corresponding base values v1 to v4. Figure 1(b) shows the version cache table, added by our proposal. In detail,  $S\_Cache$  shows that the value for k1 has been updated three times: v01 is valid from timestamp 1 to 4; v10 from 5 to 20; and v100 from 21. We can also see that k3 has been removed by version 4.

## 3.2 Snapshot reconstruction

The second pillar of our proposal is that we describe snapshot reconstruction for each transaction as a query to the common query engine. This is made possible by representing versions of items with different visibility as regular tables or collections.

Figure 2 outlines the logical query used to reconstruct each table in a transaction's snapshot. It finds out which keys in the cache (visible-to-some) are relevant considering the current transaction's starting timestamp *sts*. These keys are used to filter out the corresponding rows from the storage. The result is merged with the readable values from the cache. A complex query involving multiple tables requires computing this plan for each table.

Figure 1(c) shows the example of the reconstructed snapshot for a transaction reading from starting timestamp sts = 15. Records selected in each table are highlighted in green, and tombstones hiding items in red. In detail, k1 has been recently updated and the appropriate value corresponding to the starting timestamp of 15 is selected from *S*\_*Cache*, avoiding an even more recent value with timestamp 21. k3 is present in *S*\_*Cache* as a tombstone and thus is removed from the snapshot. Finally, k4 and k2 are obtained from the base storage table.

In short, by using a query for reconstructing the snapshot, we are able to provide isolation while, at the same time, provide a simpler alternative to special-

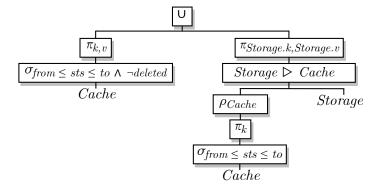

Fig. 2: Logical plan for snapshot reconstruction. *Storage* and *Cache* are the tables from Fig. 1;  $\sigma, \pi, \rho, \triangleright, \cup$  are the relational selection, projection, renaming, left anti join, and union operators, respectively.

ized transactional layers or modifications to multiple datastores. It is, however, interesting to determine to what extent the resulting performance is acceptable.

#### 3.3 Execution alternatives and optimization

The attainable performance is related to the possibility of finding an optimal physical plan for the proposed reconstruction query. Defining snapshot reconstruction as a query at the common query engine level opens up the possibility of alternative physical plans, leading to decisions by the database administrator and the automatic optimizer.

The key decision is the placement of the cache table relative to the original storage. Ideally, they would be placed right next to each other, i.e., the same datastore, providing optimal data locality and enabling the entire reconstruction plan to be pushed down to the datastore. However, since the underlying query engine might not support joining the different structures, this solution is not always viable. Therefore, the version cache can be placed in a different datastore, that should be selected to provide optimal performance for the required operations. In systems such as CloudMdsQl, auxiliary tables can be stored in the common query engine itself, instead of an external datastore.

The next decision is how to distribute the logical query plan across the common query engine and external datastores. Depending on where each cache table is placed relative to the corresponding storage table and the capabilities of the query engine in the external datastore, there are three main options for what can be delegated to the datastore, depicted in Figure 3: alternative (a) shows the ideal case of pushing the entire computation to the datastore, which should also allow for additional processing that needs to be performed over the entire snapshot to be made there; (b) sends the cache keys to the datastore to filter the storage but performs the union operation and the remaining processing in the common query engine; (c) performs only basic storage processing in the datas-

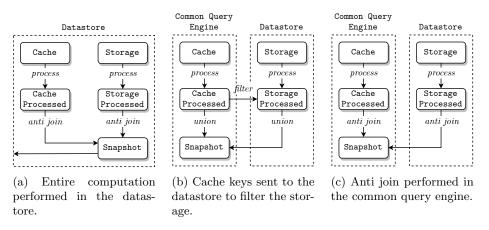

Fig. 3: Different alternatives for cache placement and snapshot computation. The "process" step here depicted can be a wide range of operators (filter, order, join, aggregate, ...) intended to be performed over the snapshot but are pushed down in order to favor index usage, reduce record materialization, and reduce data transfer.

tore (if possible), leaving the merging process and remaining processing to the common query engine.

Finally, when considering snapshot reconstruction sub-plan as part of a larger query, an optimizer should be able to globally reorder and select physical operators. For instance, when executing a join operation, the query engine might opt for first joining the caches for different tables and obtain an empty result, thus avoiding the need to filter the storage. To quickly assess if these alternatives have a substantial impact on execution time, which justifies using an optimizer, and if the resulting overhead is tolerable, we evaluate in Section 4 different plan implementations with different queries and datastores.

#### 3.4 Concurrent updates

We are focusing only on transactional snapshot reconstruction during query execution and avoiding the discussion of how update operations are handled. However, the reconstruction process needs to tolerate that operations needed for updates – producing new versions – may occur concurrently.

When a transaction is committed, new versions of data items labeled with corresponding versions need to be inserted into the cache. This can be done one item at a time without impact in reconstruction as long as no currently executing transactions have a starting timestamp equal or greater than the currently committing transaction. This is true by definition, as the starting timestamp assigned to a transaction should be the commit timestamp of the latest committed transaction. Recovery would need a re-do log to ensure that all items from committed transactions are eventually inserted in the cache.

We now consider the task which materializes cache records into the storage, i.e., *flush*, and removes them, i.e., *garbage collection*. Let us assume that a record

in the cache C,  $r_c$ , has the same key as some record  $r_s$  in the storage S, meaning  $r_c$  overwrites  $r_s$  in the snapshots of transactions with begin time greater or equal to  $r_c.from$ . We can only flush  $r_c$  if no current or future transaction can ever read  $r_s$ , i.e., the smallest begin timestamp of all currently executing transactions  $(\epsilon)$ , is greater or equal to  $r_c.from$ . This  $\epsilon$  can be easily computed with a log that stores the identifier, timestamp, and status of every transaction. When multiple versions of the same key can be flushed, the most recent one is chosen. After that, the flushed records can be safely removed from the cache.

An interesting property of this process is that it can crash at any time without compromising consistency, not requiring multi-record atomicity guarantees or needing to halt transaction execution. An incomplete flush means both flushed and non-flushed records are still present in the cache, and thus will still be considered for reads for current and future transactions. An incomplete garbage collection still has the guarantee that every removed cache record is persisted in the storage, while the remaining ones will overwrite the storage with the exact same value.

## 4 Experiment

We use a polystore inspired by CloudMdsQL [6], with MongoDB and Cassandra as datastores. Briefly, queries are written with a low code visual builder or the corresponding SQL-like language, with embedded native queries for different datastores. The common query engine is based on PostgreSQL, using the FDW interface for datastore wrappers. This system includes custom wrappers for Cassandra and MongoDB that optimize filter push-down, by combining them with the native query languages. While MongoDB's aggregation pipeline is expressive enough to build the entire snapshot natively, the same is not possible in Cassandra, and as such it relies exclusively on the common query engine to join the cache with the storage.

Therefore, we have multiple steps where the query is transformed and possibly optimized: (1) in the initial translation to PostgreSQL SQL; (2) within PostgreSQL itself; (3) in the wrapper; and finally (4) in the datastore itself. We use step 1 to determine placement and step 3 to push-down selections and projections. We have, however, limited control of step 2 in how we re-write the query in step 1 or how we provide statistics back in step 3. We deployed the system on two Google Cloud instances (8 N1 vCPUs, 8GB RAM, 500GB SDD), located on us-east1 and us-east4 (RTT of 11ms), one hosting the query engine and the other the MongoDB and Cassandra datastores. The cache sizes are set to 1% of their respective storage sizes.

Our experiment consists in running various simple queries – *select all* (returns all rows), *filter* (returns one row), small join (joins one row), large join (joins all rows), and *aggregation* (performs a sum) – on TPC-C's *order\_line* and *item* tables, stored in both MongoDB and Cassandra. By manipulating placement of tables and the common query engine, we obtain several physical plans. Considering the alternatives of Figure 3, when using MongoDB, alterna-

0	MongoDB						Cassandra						
Query	Baseline		Overhead (%)				Baseline Overhead (%				%)		
$\mathbf{type}$	(ms)	NG	NL	FJ	LJ	NI	$N\!A$	OD	(ms)	FJ	LJ	NI	OD
Select all	11682	17	151	5	7	6	8	5	15702	2	6	1	1
Filter	13	9	10	14	11	12	46	12	15	1	1	1	0
Small join	13	5	8	100	94	98	95	94	28	4	9	10	8
Large join	15266	15	156	6	10	7	5	6	19740	2	5	1	2
Aggregation	299	171	5.7K	1.4K	1.4K	1.4K	93	1.9k	8842	7	14	7	10

Table 1: Performance of different physical plans with MongoDB and Cassandra. The bordered cells mark the best plan for each query in each datastore.

 $\mathbf{NG}$  - MongoDB Native Group |  $\mathbf{NL}$  - MongoDB Native Lookup |  $\mathbf{FJ}$  - SQL Full Join |  $\mathbf{LJ}$  - SQL Left Join |  $\mathbf{NI}$  - SQL Where Not IN |  $\mathbf{NA}$  - SQL Where Not Any |  $\mathbf{OD}$  - SQL Order By + Distinct

tive (a) is implemented with a native GROUP (NG, equivalent to PostgreSQL's ORDER+DISTINCT [2]) and a native LOOKUP (NL, equivalent to PostgreSQL's LEFT JOIN [3]). With MongoDB and Cassandra, alternative (c) makes use of FULL JOIN (FJ), LEFT JOIN (LJ), NOT IN (NI), and ORDER+DISTINCT (OD). Note that each implementation generates different execution trees. Finally, we also use NOT ANY (NA) with MongoDB to implement alternative (b).

Table 1 displays the read overhead comparatively to the transaction-less alternative. The first conclusion is that different physical plans have a profound impact on query execution time, with one reaching up to  $58 \times$  the baseline! Most strikingly, *it is clear that different plans are optimal in different scenarios*, which is a compelling argument for the use of an optimizer.

Finally, these results show less than 10% of read overhead for most cases with both datastores, which compares favorably to the measured cost of corresponding transactional mechanisms in a traditional SQL database system [20]. The exception is the aggregation query with MongoDB. While the NOT ANY approach can execute the partial aggregation natively in it, greatly reducing data transfer, the engine filters the storage with the cache keys using, for this particular case, a suboptimal index scan implemented with the keys' bounds. Since each of the thousands of keys are completely different, the scan will consider thousands of bounds. For this case, a better alternative would be a *hash anti join*, which should bring the overhead closer to the other queries.

## 5 Discussion

In this paper, we address a challenge – transaction isolation in polystores – that has seen very little previous attention, even if identified as a key research challenge [28, 30]. Transactional support is a challenge even in multi-model datastores, naturally more integrated than polystores, where support for multi-model transactions seems to be non-existent [24]. The main competing approach for transactional isolation in polystores is Polypheny-DB [32]. In contrast to our proposal, which aims at running readonly transactions with little interference and at fine-grained conflict resolution for update transactions, Polypheny-DB assumes two-phase locking with coarse granularity, which limits concurrent updates and makes them conflict with readonly transactions.

We are also aware of a different proposal that has been prototyped in Cloud-MdsQL [22], as part of the same research project. Like our current proposal, it aimed at Snapshot Isolation and fine-grained conflict resolution but it relied on the implementation, from scratch, of a custom wrapper or even core changes, to each datastore. It also assumed the version cache is always co-located, which often resulted in changing the native schema.

Similar motivation can be found in DeltaLake [7], aimed at incremental loading or correction of data in a data lake with coarse-granularity. In contrast to our proposal, it is not aimed at polystores but only at data in Parquet files directly managed by Spark. Therefore, snapshot reconstruction in DeltaLake boils down to reading the right subset of file fragments, making updates and removals very costly as a new version of the affected files needs to be written. It is also not clear how it would be extended to polystores.

Our approach is to define transactional isolation in terms of additional tables, managed themselves within the polystore, and generic queries that can be mapped to a common query engine layer and multiple datastores. This takes advantage of query optimization to achieve the optimal execution plan for each particular polystore configuration. In fact, a preliminary experiment shows that the overhead of transactional isolation is comparable to what has been measured in traditional SQL systems [20].

An interesting outcome of this experiment regards the feasibility of the proposed approach: To what extent keeping updated versions in a separate table can be reconciled with full use of the interface of each datastore? Namely, can a native query for some datastore always be modified to account for such versions? In our experiment, this is very easy to do with a key-value store such as Cassandra, where obsolete versions returned from the datastore can easily be replaced by the correct versions from the cache. Our experience with MongoDB is different: We cannot easily patch the result from a native query, which can be an arbitrarily complex "aggregation pipeline." On the other hand, this makes MongoDB expressive enough that the query can be modified to the reconstruction by itself. We postulate that this might be generally true: Whenever the native query engine is complex enough to make it hard to patch the result, it should be expressive enough to be itself used for reconstruction.

The main threat to the validity of our experiment is that we omit the write path. We expect to approach this by defining how updates on a view should be translated to changes in the cache table, which can be implemented, for example, using INSTEAD OF triggers or rules [4]. This possibility is limited by known bounds on updatable views as the reverse mapping may not always exist [13] and the challenges of translating an update u to a view V into a set of updates

U to the underlying data D, namely [15, 16]. Additionally, we have to consider multiple data models and, in the CloudMdsQL, the effect of ad-hoc views, for which we can resort to bi-directional transformations, with weaker guarantees on update properties [11, 25]. Finally, we have to coordinate the recovery of heterogeneous multi-statement transactions with the various guarantees of individual datastores.

We can thus identify several lessons learned and outstanding challenges for transactional polystores:

Optimization and DBA are needed. We have shown that structuring snapshot reconstruction as a data processing problem allows optimization (different plans are optimal in different conditions) and provides an opportunity for a DBA to intervene.

Useful for different datastores. Datastores with a more complex QE make it harder to store changes and reconstruct the snapshot outside (e.g. MongoDB) than simple key-value stores, but on the other hand, they make it easier to use their own QE for reconstruction, which makes the approach feasible across a large spectrum of datastores.

Datastore interfaces matter. It is highly relevant that the data-store language is amenable to processing and manipulation, without having to rewrite the parser. For instance, MongoDB's aggregation pipeline is much easier to handle than the SQL-like language in Cassandra. It is thus a challenge to achieve this and still be user-friendly for writing native queries.

Various isolation criteria are possible. Polystores are inherently distributed and likely make strict snapshot isolation problematic. Moreover, it is likely that the "one size does not fit all" motto is also true in terms of isolation level. A possible alternative is a relaxed criterion such as TOPSI [18].

Update processing is an open problem. Updates issued at the common QE level are issued on views. This means that they have to be translated back to the original data model for the underlying datastore.

Interaction with native readers and writers is an open problem. Our proposal provides transactional isolation when all readers and writers access datastores through the common query engine. A consistent view of a prefix of updates to native readers should also be possible by judiciously scheduling checkpointing operations. It is unclear, however, if it is possible to do the reverse: Allowing native clients to update datastores without disturbing isolation.
